

**Time Spent:** 1 hour

**Collaborators and Resources:** Nathaniel MacArthur-Warner and I discussed what max flow says about the graph

---

## Problem 2

In this problem we're given the definition of edge connectivity and our task is to find a way to compute edge connectivity (defined as the minimum number  $k$  of edges that must be removed to disconnect  $G$ ) by running a maximum-flow algorithm on a collection of flow networks, each having  $O(|V|)$  vertices and  $O(|E|)$  edges. The way we conceptualized this was to say that we look at each path from  $s$  to  $t_i$  where  $t_i \neq s$  and then we run a max-flow algorithm on each case ...

1. Given an undirected graph  $G = (V, E)$
2. Initialize an empty array  $A$
3. For each edge  $e = (s, t) \in E$ 
  - (a) Remove  $e$
  - (b) Create two directed edges  $e_1 = (s, t)$  and  $e_2 = (t, s)$  and set each of their capacities to 1
4. Denote one of the vertices  $s$  to be our starting point
5. For each vertex  $t_i \in V$  such that  $t_i \neq s$ 
  - (a) Run Ford-Fulkerson to find the maximum flow  $f^*$  between  $s$  and  $t_i$
  - (b) Add  $f^*$  to  $A$
6. Return  $\min(A)$

**Claim 1.** The algorithm works correctly and returns the minimum number  $k$  of edges that must be removed to disconnect  $G$  (the edge connectivity)

*Proof.* Divide the nodes of  $G$  into two sets,  $A$  and  $B$  where  $s \in A$  and  $s \notin B$ . Select any vertex in  $B$  and call it  $t$ . The algorithm I have described simply determines the maximum flow between  $s$  and  $t$  using the Ford-Fulkerson algorithm. Now, having computed the maximum value  $f^*$  of an  $s$ - $t$  flow we know that this is equal to the minimum capacity of an  $s$ - $t$  cut (K-T 7.13). Furthermore, since all the capacities are 1 we know that the minimum capacity of an  $s$ - $t$  cut is equal to the minimum number of edges needed to disconnect  $s$  from  $t$ . Taking the minimum out of all values of  $f^*$  is going to give us the way to disconnect the graph removing the fewest number of edges possible. So we know that the algorithm works.  $\square$

**Claim 2.** The algorithm runs in  $O(|V| \cdot |E|^2)$  time.

*Proof.* Because the Ford-Fulkerson algorithm runs in  $O(|E|f^*)$  time where  $m$  is the number of edges and  $f^*$  is the maximum flow found, we have one part of our run-time. Because the Ford-Fulkerson algorithm is applied to every pair of vertices  $(s, t_i)$ , it's going to run a maximum of  $|V|$  times since there are  $V-1$  choices for  $t_i$ . The maximum flow  $f^*$  is always upper bounded by the number of edges  $|E|$  and so we know that in total the algorithm will run in  $O(|V| \cdot |E|^2)$  time. Constructing the directed graph also takes  $O(|E|)$  time, however as the graph gets larger we will see that this initial step becomes inconsequential in terms of running time.  $\square$
